Exploiting Structure of Uncertainty for Efficient Matroid Semi-Bandits

Pierre Perrault 1 2 Vianney Perchet 2 3 Michal Valko 1 4

Abstract

We improve the efficiency of algorithms for stochastic combinatorial semi-bandits. In most interesting problems, state-of-the-art algorithms take advantage of structural properties of rewards, such as independence. However, while being optimal in terms of asymptotic regret, these algorithms are inefficient. In our paper, we first reduce their implementation to a specific submodular maximization. Then, in case of matroid constraints, we design adapted approximation routines, thereby providing the first efficient algorithms that rely on reward structure to improve regret bound. In particular, we improve the state-of-the-art efficient gap-free regret bound by a factor $\sqrt{m/\log m}$, where $m$ is the maximum action size. Finally, we show how our improvement translates to more general budgeted combinatorial semi-bandits.

1. Introduction

Stochastic bandits model sequential decision-making in which an agent selects an arm (a decision) at each round and observes a realization of the corresponding unknown reward distribution. The goal is to maximize the expected cumulative reward, or equivalently, to minimize the expected regret, defined as the difference between the expected cumulative reward achieved by an oracle algorithm always selecting the optimal arm and that achieved by the agent. To accomplish this objective, the agent must trade-off between exploration (gaining information about reward distributions) and exploitation (using greedily the information collected so far) as it was already discovered by Robbins (1952). Bandits have been applied to many fields such as mechanism design (Mohri & Munoz, 2014), search advertising (Tran-Thanh et al., 2014), and personalized recommendation (Li et al., 2010). We improve the computational efficiency (i.e., the time and space complexity) of their combinatorial generalization, in which the agent selects at each round a subset of arms, that we refer to as an action in the rest of the paper (Cesa-Bianchi & Lugosi, 2012; Gai et al., 2012; Audibert et al., 2014; Chen et al., 2014).

Different kinds of feedback provided by the environment are possible. First, with bandit feedback (also called full bandit or opaque feedback), the agent only observes the total reward associated to the selected action. Second, with semi-bandit feedback, the agent observes the partial reward of each base arm in the selected action. Finally, with full information feedback, the agent observes the partial reward of all arms. We give results for semi-bandit feedback only.

There are two main questions that come up with combinatorial (semi)-bandits: 1° How can the stochastic structure of the reward vector be exploited to reduce the regret? and 2° Can algorithms be efficient? Combes et al. (2015) answer the first question assuming that reward distributions are mutually independent. Later, Degenne & Perchet (2016) generalize the algorithm of Combes et al. (2015) to a larger class of sub-Gaussian rewards by exploiting the covariance structure of the arms. They also show the optimality of proposed algorithms, in particular, that an upper bound on their regret matches the asymptotic gap dependent lower bound of this class. However, algorithms of Combes et al. (2015) and Degenne & Perchet (2016) are computationally inefficient. The second question is studied by Kveton et al. (2015), who give an efficient algorithm based on the UCB algorithm of Auer et al. (2002). While being efficient, the algorithm of Kveton et al. (2015) assumes the worst case class of arbitrary correlated rewards, i.e., it does not exploit any properties of rewards and therefore does not match the lower bound of Degenne & Perchet (2016).

On the other hand, efficient algorithms for matroid (Whitney, 1935) semi-bandits exist (Kveton et al., 2014; Talebi & Proutiere, 2016) and their regret bounds match the asymptotic gap dependent lower bound, which is the same for both sub-Gaussian and arbitrary correlated rewards. Among these algorithms, the state-of-the-art gap-free regret bound is of order $O(\sqrt{nmT\log T})$, where $T$ is the number of rounds, $n$ is the number of base arms, and $m$ is the maximum action size (Kveton et al., 2014).

\footnote{Any dependence can exist between rewards.}

Our contributions In this paper, we show how algorithms of Combes et al. (2015) and Degenne & Perchet (2016) can be efficiently approximated for matroid. This improves the bound of Kveton et al. (2014) by a factor $\sqrt{m} / \log(m)$ for the class of sub-Gaussian rewards. We first locate the source of inefficiency of these algorithms: At each round, they have to solve a submodular maximization problem. We then provide efficient, adapted LOCALSEARCH and GREEDY-based algorithms that exploit the submodularity to give approximation guarantees on the regret upper bound. These algorithms can be of independent interest. We also extend our approximation techniques to more challenging budgeted combinatorial semi-bandits via binary search methods and exhibit the same improvement for this setting as well.

Related work Efficiency in combinatorial bandits, or more generally, in linear bandits with a large set of arms is an open problem. Some methods, such as convex hull representation, (Koolen et al., 2010), hashing (Jun et al., 2017), or DAG-encoding (Sakaue et al., 2018) reduce the algorithmic complexity. For semi-bandit feedback, in the adversarial case, Neu & Bartók (2013) proposed an efficient implementation via geometric resampling. In the stochastic case, many efficient Bayesian algorithms exist (see e.g., Russo & Van Roy, 2013; Russo & Roy, 2016), although they are only shown to be optimal for Bayesian regret.2

2. Background

We denote the set of arms by $[n] \triangleq \{1, 2, \ldots, n\}$, we typeset vectors in bold and indicate components with indices, i.e., $a = (a_i)_{i \in [n]} \in \mathbb{R}^n$. We let $P([n]) \triangleq \{A, A \subset [n]\}$ be the power set of $[n]$. Let $e_i \in \mathbb{R}^n$ denote the $i$th canonical unit vector. The incidence vector of any set $A \in P([n])$ is

$$e_A \triangleq \sum_{i \in A} e_i.$$

The above definition allows us to represent a subset of $[n]$ as an element of $\{0, 1\}^n$. We denote the Minkowski sum of two sets $Z, Z' \subset \mathbb{R}^n$ as $Z + Z' \triangleq \{z + z', z \in Z, z' \in Z'\}$, and $Z + z' \triangleq Z + \{z'\}$. Let $A \subset P([n])$ be a set of actions. We define the maximum possible cardinality of an element of $A$ as $m \triangleq \max |A|, A \in A$.

2.1. Stochastic Combinatorial Semi-Bandits

In combinatorial semi-bandits, an agent selects an action $A_t \in A$ at each round $t \in \mathbb{N}^+$, and receives a reward $e_{A_t}^\top X_t$, where $X_t \in \mathbb{R}^n$ is an unknown random vector of rewards. The successive reward vectors $(X_t)_{t \geq 1}$ are i.i.d., with an unknown mean $\mu^* \triangleq \mathbb{E}[X] \in \mathbb{R}^n$, where $X = X_1$. After selecting an action $A_t$ in round $t$, the agent observes the partial reward of each individual arm in $A_t$. The goal of the agent is to minimize the expected regret, defined with $A^* \in \arg \max_{A \in A} e_A^\top \mu^*$ as

$$R_T \triangleq \mathbb{E} \left[ \sum_{t=1}^T (e_{A_t} - e_{A^*})^\top X_t \right].$$

For any action $A \in A$, we define its gap as the difference $\Delta(A) \triangleq (e_{A} - e_{A^*})^\top \mu^*$. We then rewrite the expected cumulative regret as $R_T = \mathbb{E} \left[ \sum_{t=1}^T \Delta(A_t) \right]$. Finally, we define $\Delta \triangleq \min_{A \in A, \Delta(A) > 0} \Delta(A)$.

Combinatorial semi-bandits have been introduced by Cesab-Bianchi & Lugosi (2012). More recently, different algorithms have been proposed (Talebi et al., 2013; Combes et al., 2015; Kveton et al., 2015; Degenne & Perchet, 2016), depending whether the random vector $X$ satisfies specific properties. Some of these properties commonly assumed are a subset of the following ones:

(i) $X_1, \ldots, X_n \in \mathbb{R}$ are mutually independent,

(ii) $X_1, \ldots, X_n \in \mathbb{R}$ are arbitrary correlated,

(iii) $X \in [-1, 1]^n$,

(iv) $X \in \mathbb{R}^n$ is multivariate sub-Gaussian, i.e., $\mathbb{E} e^{X^\top (X - \mu^*)} \leq e^{\|X\|^2/2}, \forall \lambda \in \mathbb{R}^n$.

(v) $X \in \mathbb{R}^n$ is component-wise sub-Gaussian, i.e., $\mathbb{E} e^{X_i^\top (X_i - \mu_i^*)} \leq e^{\lambda_i^2/2}, \forall i \in [n], \forall \lambda \in \mathbb{R}^n$.

2.2. Lower Bounds

Combining some of the above properties, we consider different classes of possible distributions for $X$. In Table 1, we show two existing gap-dependent lower bounds on $R_T$ that depend on the respective class. They are valid for at least one distribution of $X$ belonging to the corresponding class, one combinatorial structure $A \subset P([n])$, and for any consistent algorithm (Lai & Robbins, 1985), for which the regret on any problem verifies $R_T = o(T^n)$ as $T \to \infty$ for all $a > 0$. Table 1 suggests that a tighter regret rate can be reached with some prior knowledge on the random vector $X$.

3. (In)efficiency of Existing Algorithms

In this section, we discuss the efficiency of existing algorithms matching the lower bounds in Table 1. We consider that an algorithm is efficient as soon as the time and space complexity for each round $t$ is polynomial in $n$ and polylog-

3.1. A Generic Algorithm

As mentioned above, the action set \(A_t\) is selected based on the feedback received up to round \(t-1\). A common statistic computed from this feedback is the empirical average of each arm \(i \in [n]\), defined as

\[
\mu_{i,t}^u = 0, \quad \forall t \geq 2, \quad \mu_{i,t-1} = \frac{\sum_{u \in [t-1]} \mathbb{I}\{i \in A_u\} X_{i,u}}{N_{i,t-1}},
\]

where \(\forall t \geq 1, \ N_{i,t-1} = \sum_{u \in [t-1]} \mathbb{I}\{i \in A_u\}\). Many combinatorial semi-bandit algorithms, in particular, those listed in Table 2, can be seen as a special case of Algorithm 1 for different confidence regions \(C_t\) around \(\mu_{i,t-1}\).

**Algorithm 1** Generic confidence-region-based algorithm.

At each round \(t\) :
- Find a confidence region \(C_t \subset \mathbb{R}^n\).
- Solve the bilinear program
  \[
  (\mu_t, A_t) \in \arg\max_{\mu \in C_t, A \in A} e_A^T \mu.
  \]
- Play \(A_t\).

We further assume that \(C_t\) is defined through some parameters \(p, r \in \{1, \infty\}\), and some functions \(g_{i,t}, i \in [n]\) by

\[
C_t \triangleq [-r, r]^n \cap \left\{ \delta \in \mathbb{R}^n : \| (g_{i,t}(\delta_i)) \|_p \leq 1 \right\},
\]

where \(g_{i,t} = 0\) if \(N_{i,t-1} = 0\) and, otherwise, is convex, strictly decreasing on \([-r - \pi_{i,t-1}, 0]\) and strictly increasing on \([0, r - \pi_{i,t-1}]\) such that \(g_{i,t}(0) = 0\). Typically, \(r = 1\) under assumption \((iii)\) and \(r = \infty\) otherwise. Table 2 lists variants of Algorithm 1, with the corresponding reward class under which they can be used. Each of these algorithms is matching the lower bound corresponding to the respective reward class considered in Table 1, i.e., \(R_T\) is a ‘big \(O\)’ of the lower bound, up to a polylogarithmic factor in \(m\) (Degenne & Perchet, 2016). Notice that THOMPSON SAMPLING is not an instance of Algorithm 1. However, we are not aware of any tight analysis: The one by Wang & Chen (2018) matches the lower bound \(nm \log(T)/\Delta\), but only for mutually independent rewards, where the lower bound is \(n \log(T)/\Delta\). The regret upper bound of algorithms in Table 1 with \(p = 1\) has an additive constant term w.r.t. \(T\) but exponential in \(n\), which can be replaced with a different analysis to get either:

- an exponential term in \(m\) plus a term of order \(1/\Delta^2\),
- a term of order \(1/\Delta^2\) — by changing \(\log(t)\) to \(\log(t) + m \log \log(t)\) in the algorithm,
- or can be removed — by changing \(\log(t)\) to \(\log(t) + n \log \log(t)\) in the algorithm.

On one hand, the arbitrary correlated case can be considered as solved, since the matching lower bound algorithm CUCB (Kveton et al., 2015) is efficient.\(^4\) On the other hand, considering the reward class given by the first line of Table 1, the known algorithms that match the lower bound are inefficient.\(^5\) We further discuss the efficiency of Algorithm 1 in the following subsection.

3.2. Submodular Maximization

In Algorithm 1, only \(A_t\) needs to be computed. It is a maximizer over \(\mathcal{A}\) of the set function

\[
\mathcal{P}([n]) \rightarrow \mathbb{R}, \quad A \mapsto \max_{\mu \in C_t} e_A^T \mu.
\]

We can easily evaluate the function (1) above for some set \(A \in \mathcal{P}([n])\), since it only requires solving a linear optimization problem on the convex\(^6\) set \(C_t\). In Proposition 1, we

\(^3\)Arithmetic in \(t\). Notice that the per-round complexity depends substantially on \(\mathcal{A}\). We assume \(\mathcal{A}\) is such that linear optimization problems on \(\mathcal{A}\) — of the form \(\max_{A \in \mathcal{A}} e_A^T \delta\) for some \(\delta \in \mathbb{R}^n\) — can be solved efficiently. As a consequence, an agent knowing \(\mu^*\) can efficiently compute \(A^*\). Assuming efficient linear maximization is crucial (cf. Neu & Bartók, 2013; Combes et al., 2015; Kveton et al., 2015; Degenne & Perchet, 2016). Without this assumption, e.g., for \(\mathcal{A}\) being dominating sets in a graph, even the offline problem cannot be solved efficiently, and we would have to consider the notion of approximation regret instead, as was done by Chen et al. (2013).

\(^4\)In Theorem 1, we recover that \(A_t\) is computed by Algorithm 1 by solving a linear optimization problem.

\(^5\)\(A\) may have up to \(2^n\) elements.

\(^6\)\(C_t\) is convex since functions \(g_{i,t}\) are convex.
show that in some cases, the evaluation can be even simpler. However, maximizing the function (1) over a combinatorial set $A$ is not straightforward. Before studying this function more closely, Definition 1 recalls some well-known properties that can be satisfied by a set function $F : \mathcal{P}([n]) \to \mathbb{R}$.

**Definition 1.** A set function $F$ is:

- normalized, if $F(\emptyset) = 0$,
- linear (or modular) if $F(A) = e_A^T \delta + b$, for some $\delta \in \mathbb{R}^n$, $b \in \mathbb{R}$,
- non-decreasing if $F(A) \leq F(B)$ for all $A \subseteq B \subseteq [n]$,
- submodular if for all $A, B \subseteq [n]$,
  
  $$F(A \cup B) + F(A \cap B) \leq F(A) + F(B).$$

Equivalently, $F$ is submodular if for all $A \subseteq B \subseteq [n]$, and $i \notin B$, $F(A \cup \{i\}) - F(A) \geq F(B \cup \{i\}) - F(B)$.

The function (1) is clearly normalized, and it can be decomposed into two set functions in the following way,

$$\forall A \subseteq [n], \max_{\mu \in \mathcal{C}} e_A^T \mu = e_A^T \mathbf{1}_{n} + \max_{\delta \in [n] \setminus \mathbf{1}_{n}} e_A^T \delta.$$

The linear part $A \mapsto e_A^T \mathbf{1}_{n}$ is efficiently maximized alone, we thus focus on the other part, $A \mapsto \max_{\delta \in [n] \setminus \mathbf{1}_{n}} e_A^T \delta$, usually called an exploration bonus. It aims to compensate for the negative selection bias of the first term. We define

$$\mathcal{C}_t^+ \triangleq [-r, r]^n \cap \left\{ \delta \in \mathbb{R}^n, \| (g_{i,t}(\delta_t))_i \|_p \leq 1 \right\}$$

and rewrite $A \mapsto \max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta$ through Lemma 1.

**Lemma 1.** For all $A \in \mathcal{P}([n])$, $\max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta = \max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta$.

The lemma holds as $\{ (\delta_t^+)_i, \delta \in \mathcal{C}_t \setminus \mathbf{1}_{n} \} \subseteq \mathcal{C}_t \setminus \mathbf{1}_{n}$. As a corollary, this set function is non-negative, and non-decreasing. It can be written in closed form under additional assumptions, see Proposition 1 and Example 1.

**Proposition 1.** Let $A \in \mathcal{P}([n])$, $t \in \mathbb{N}^*$, $p = 1$. Assume that for all $i \in A$, $g_{i,t}$ has a strictly increasing, continuous derivative $g_{i,t}$, defined on $[0, \infty)$, $r - \pi_{i,t-1}$. For $i \in A$, let

$$f_i(\lambda) \triangleq \begin{cases} g_{i,t}^{-1}(1/\lambda) \quad & \text{if } 1/\lambda < g_{i,t}(r - \pi_{i,t-1}), \\ r - \pi_{i,t-1} & \text{otherwise,} \end{cases}$$

defined for $\lambda \geq 0$. Then, the smallest $\lambda^*$ satisfying

$$\left( \delta^*_t \right)_i \triangleq (\{i \in A\} f_i(\lambda^*))_i \in \arg \max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta.$$

is such that

$$\left( \delta^*_t \right)_i \triangleq (\{i \in A\} f_i(\lambda^*))_i \in \arg \max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta.$$

The proof of Proposition 1 can be found in Appendix A. An important use-case example of Proposition 1 is the following

**Example 1.** Let $A \in \mathcal{P}([n])$, $t \in \mathbb{N}^*$. If for all $i \in [n]$, $g_{i,t} = (\cdot)^2 \alpha_{i,t}$ for some $\alpha_{i,t} > 0$, and $r = \infty$, $p = 1$, then

$$\max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta = \sqrt{e_A^T \left( \frac{1}{\alpha_{i,t}} \right)_i}. $$

Indeed, since the maximizer $\delta^*$ lies at the boundary, $\max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta = \max_{\delta \in \mathbb{R}_+^{n}, \sum_{i \in [n]} \alpha_{i,t} \delta_i = 1} e_A^T \delta$, and from the first-order optimality condition we deduce that $e_A = 2 \lambda^*(\alpha_{i,t} \delta^*_t)_i$, i.e., $\delta^*_t = (\{i \in A\} / 2 \lambda^* \alpha_{i,t}$, where $\lambda^*$ is necessarily $\frac{1}{2} \sqrt{e_A^T \left( 1/\alpha_{i,t} \right)_i}$. We thus recover the ESCB’s exploration bonus for $\alpha_{i,t} = N_{i,t-1} / log t$.

**Remark 1.** The proof of Proposition 1 follows the same technique as the proof of Theorem 4 by Combes et al. (2015) for developing the computation of the ESCB-KL exploration bonus.

Example 1 is a specific case where the exploration bonus $A \mapsto \max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta$ has a particularly simple form: It is the square root of a non-decreasing linear set function. Such a set function is known to be submodular (Stobbe & Krause, 2010). This interesting property helps for maximizing the function (1). In Theorem 1, we prove that $A \mapsto \max_{\delta \in \mathcal{C}_t^+ \setminus \mathbf{1}_{n}} e_A^T \delta$ is in fact always submodular.
Theorem 1. The following two properties hold.

- For \( p = \infty \), \( A \mapsto \max_{\delta \in C^+ I} \varepsilon_A^T \delta \) is linear.
- For \( p = 1 \), \( A \mapsto \max_{\delta \in C^+ I} \varepsilon_A^T \delta \) is submodular.

The proof is deferred to Appendix B and uses a result on polymatroids by He et al. (2012). Theorem 1 first implies the efficiency of any variant of Algorithm 1 with \( p = \infty \), since it reduces to optimizing a linear set function over \( A \). Theorem 1 also yields that when the reward class is strength to target the tighter lower bound \( n \log(T)/\Delta \). Algorithm 1 reduces to maximizing a submodular set function over \( A \) (the sum of a linear and a submodular function is submodular). Submodular maximization problems have been applied in machine learning before (see e.g., Krause & Golovin, 2011; Bach, 2011), however, maximizing a submodular function \( F \), even for \( A = \{A, |A| \leq m\} \) and \( F \) non-decreasing, is NP-Hard in general (Schipper, 2008), with an approximation factor of \( 1 + 1/(\epsilon - 1) \) by the GREEDY algorithm (Nemhauser et al., 1978). This is problematic as the typical analysis is based on controlling with high probability the error \( \Delta(A_{t}) \) at round \( t \) using \( \max_{\delta \in C_{t-I}} \varepsilon_{A_{t}}(|\delta_{i}|) \), which converges to zero as \( C_{t-I} \) becomes increasingly tight along axis \( i \in A_{t} \) (because counters \( N_{i,t-1} \) increases for \( i \in A_{t} \)). More precisely, since \( \mu^* \) belongs with high probability to the confidence region \( C_{t}, \mu^{*} - \mu \) belongs with high probability to \( C_{t-I} \). For \( \kappa \geq 1 \), a \( \kappa \)–approximation algorithm for maximizing the function (1) would only guarantee the following:

\[
\Delta(A_{t}) = (e_{A_{t}} - e_{A_{t}})^{T}\mu^{*} \\
\leq \max_{\mu \in C_{t}} e_{A_{t}}^{T}\mu - e_{A_{t}}^{T}\mu^{*} \\
= \kappa \max_{\mu \in C_{t}} e_{A_{t}}^{T}\mu - e_{A_{t}}^{T}\mu^{*} \\
\leq \kappa \max_{\mu \in C_{t}} e_{A_{t}}^{T}\mu - e_{A_{t}}^{T}\mu^{*} \\
= \kappa \max_{\delta \in C_{t-I}} e_{A_{t}}^{T}\delta + e_{A_{t}}^{T}(\mu - \mu^{*}) + (\kappa - 1)e_{A_{t}}^{T}\mu \\
\leq (\kappa + 1) \max_{\delta \in C_{t-I}} e_{A_{t}}^{T}(|\delta_{i}|) + (\kappa - 1)e_{A_{t}}^{T}\mu \tag{2}
\]

If \( \kappa \neq 1 \), the term \( (\kappa - 1)e_{A_{t}}^{T}\mu \) gives linear regret bounds. In the next section, with a stronger assumption on \( A \) (but for which submodular maximization is still NP-Hard), we show that both parts of the objective can have different approximation factors. More precisely, we show how to approximate the linear part with factor \( 1 \), and the submodular part with a constant factor \( \kappa \geq 1 \). Then, (2) can be replaced by

\[
\kappa \cdot \max_{\mu \in C_{t-I}} e_{A_{t}}^{T}\mu + 1 \cdot e_{A_{t}}^{T}\mu \tag{3}
\]

Therefore, in (3), the extra \( \kappa - 1 \) term is removed.

4. Efficient Algorithms for Matroid Constraints

In this section, we will consider additional structure on \( A \), using the notion of matroid, recalled below.

Definition 2. A matroid is a pair \( ([n], I) \), where \( I \) is a family of subsets of \([n]\), called the independent sets, with the following properties:

- The empty set is independent, i.e., \( \emptyset \in I \).
- Every subset of an independent set is independent, i.e., for all \( A \in I \), if \( A' \subseteq A \), then \( A' \in I \).
- If \( A \) and \( B \) are two independent sets, and \( |A| > |B| \), then there exists \( x \in A \backslash B \) such that \( B \cup \{x\} \in I \).

Matroids generalize the notion of linear independence. A maximal (for the inclusion) independent set is called basis and all bases have the same cardinality \( m \), which is called the rank of the matroid (Whitney, 1935). Many combinatorial problems such as building a spanning tree for network routing (Oliveira & Pardalos, 2005) can be expressed as a linear optimization on a matroid (see Edmonds & Fulkerson, 1965 or Perfect, 1968, for other examples).

Let \( I \subseteq \mathcal{P}([n]) \) be such that \( ([n], I) \) forms a matroid. Let \( B \subseteq I \) be the set of bases of the matroid \( ([n], I) \). In the following, we may assume that \( A \) is either \( I \) or \( B \). We also assume that an independence oracle is available, i.e., given an input \( A \subseteq [n] \), it returns \( \text{true} \) if \( A \in I \) and \( \text{false} \) otherwise. Maximizing a linear set function \( L \) on \( A \) is efficient, and it can be done as follows (Edmonds, 1971): Let \( \sigma \) be a permutation of \([n]\) and \( j \) an integer such that \( j = m \) in case \( A = B \) and otherwise, \( j \) satisfies

\[
\ell_{1} \geq \cdots \geq \ell_{j} \geq 0 \geq \ell_{j+1} \geq \cdots \geq \ell_{n},
\]

where \( \ell_{i} = L(\{\sigma(i)\}) \) \( \forall i \in [n] \). The optimal \( S \) is built greedily starting from \( S = \emptyset \), and for \( i \in [j], \sigma(i) \) is added to \( S \) only if \( S \cup \{\sigma(i)\} \in I \).

Matroid bandits with \( A = B \) has been studied by Kveton et al. (2014); Talebi & Proutiere (2016). In this case, the two lower bounds in Table 1 coincide to \( \Omega(n \log(T)/\Delta) \), and CUCB reaches it, with the following gap-free upper bound:

\[
R_{T}(\text{CUCB}) = O(\sqrt{nmT \log T}).
\]

Assuming sub-Gaussian rewards to use any Algorithm of Table 2 with \( p = 1 \) would tighten (Dehne & Perchet, 2016) this gap-free upper bound to \( O(\sqrt{n \log^{*} mT \log T}) \). Notice, due to the \( \sqrt{\log T} \) factor, this does not contradict the \( \Omega\left(\sqrt{nmT}\right) \) gap-free lower bound for multi-play bandits.

In the rest of this section, we provide efficient approximation routines to maximize the function (1) on \( A = I \) and \( B \) without having the extra undesirable term \( (\kappa - 1)e_{A_{t}}^{T}\mu \), that a standard \( \kappa \)–approximation algorithm would suffer.
Therefore, using these routines in Algorithm 1 do not alter its regret upper bound.

Let $L$ be a normalized, linear set function, that will correspond to the linear part $A \mapsto e_A^T \pi_{t-1}$; and let $F$ denote a normalized, non-decreasing, submodular function, that will correspond to the submodular part $A \mapsto \max_{\delta \in C_t^+} e_A^T \delta$. Unless stated otherwise, we further assume that $F$ is positive (for $A \neq \emptyset$). This is a mild assumption as it holds for $A \mapsto \max_{\delta \in C_t^+} e_A^T \delta$ in the unbounded case, i.e., if $(iii)$ is not assumed and $r = \infty$. If $(iii)$ is true, then adding an extra $e_A^T \left( \frac{1}{\sqrt{n_i+t-1}} \right)$ term will recover positivity and increase the regret upper bound by only an additive constant. In the following subsections, we will provide algorithms that efficiently outputs $S$ such that

$$L(S) + \kappa F(S) \geq L(O) + F(O), \quad \forall O \in A,$$

(4)

with some appropriate approximation factor $\kappa \geq 1$. It is possible to efficiently output $S_1$ and $S_2$ such that we get $L(S_1) \geq L(O_1)$ and $\kappa F(S_2) \geq F(O_2)$ for any $O_1, O_2 \in A$. Although we can take $O_1 = O_2$, $S_1$ and $S_2$ are not necessarily equal, and (4) is not straightforward. The last subsection is where we apply this approach to budgeted matroid semi-bandits.

### 4.1. Local Search Algorithm

In this subsection, we assume that $A = \mathcal{I}$. In Algorithm 2, we provide a specific instance of LOCAL SEARCH that we tailored to our needs to approximately maximize $L + F$.

It starts from the greedy solution $S_{\text{init}} = \arg \max_{A \in \mathcal{I}} L(A)$. Then, Algorithm 2 repeatedly tries three basic operations in order to improve the current solution. Since every $S \in A$ can potentially be visited, only significant improvements are considered, i.e., improvements greater than $\frac{\varepsilon_m}{m} F(S)$ for some input parameter $\varepsilon > 0$. The smaller $\varepsilon$ is, the higher complexity will be. Notice the improvement threshold $\frac{\varepsilon_m}{m} F(S)$ does not depend on $L$. In fact, this is crucial to ensure that the approximation factor of $L$ is 1. However, this can increase the time complexity. To prevent this increase, the second essential ingredient is the initialization, where only $L$ plays a role.

In Theorem 2, we state the approximation guarantees for Algorithm 2 and its time complexity. The proof of Theorem 2 is in Appendix C. For $C_t$ given by any algorithm of Table 2, $F(A) = \max_{\delta \in C_t^+} e_A^T \delta$, and $\varepsilon = 1$, the time complexity is bounded by $O(n^2 \log(mt))$, and is thus efficient. Another algorithm enjoying an improved time complexity is provided in the next subsection, in the case where $A = \mathcal{B}$.

**Theorem 2.** Algorithm 2 outputs $S \in \mathcal{I}$ such that

$$L(S) + 2(1 + \varepsilon) F(S) \geq L(O) + F(O), \quad \forall O \in \mathcal{I}.$$
Theorem 4. Functions of the chosen action \( A \) assume that total costs/rewards are non-negative linear set. It minimizes the ratio where the averages are replaced by \( \frac{L_1}{L_2 + F_2} \). Indeed, \( (L_1 - F_1)/(L_2 + F_2) \) is a high-probability lower bound on the ratio of expectation, so by monotonicity of \( x \mapsto x^+ \) on \( \mathbb{R} \), \((L_1 - F_1)/(L_2 + F_2)\) is also a high-probability lower bound. We assume \( L_2 \) is normalized, but not necessarily \( L_1 \). \( L_1(\emptyset) \) can be seen as an entry price. When \( L_1 \) is normalized, we assume that \( \emptyset \) is not feasible.

Remark 2. Notice, if \( A = \emptyset \), and \( L_1 \) is normalized, then there is an optimal solution of the form \( \{s\} \in \mathcal{I} \). If \( L_1 - F_1 \) is negative for some \( S = \{s\} \subset \mathcal{I} \), then such \( S \) is a minimizer. Otherwise, by submodularity (and thus subadditivity, since we consider normalized functions), \( L_1 - F_1 \) is non-negative, and we have

\[
\frac{L_1(S) - F_1(S)}{L_2(S) + F_2(S)} \geq \frac{\sum_{s \in S} L_1(\{s\}) - F_1(\{s\})}{\sum_{s \in S} L_2(\{s\}) + F_2(\{s\})} \geq \min_{s \in S} \frac{L_1(\{s\}) - F_1(\{s\})}{L_2(\{s\}) + F_2(\{s\})}.
\]

Algorithm 3 \textsc{Greedy} for maximizing \( L + F \) on \( \mathcal{B} \).

\begin{algorithm}
\caption{Greedy for maximizing \( L + F \) on \( \mathcal{B} \).}
\begin{algorithmic}
\State \textbf{Input}: \( L, F, \mathcal{I}, m \).
\State \textbf{Initialization}: \( S \leftarrow \emptyset \).
\For {\( i \in [k] \)}
\State \( x \in \arg \max_{x \notin S, s \cup \{x\} \in \mathcal{I}} (L + F)(S \cup \{x\}) \).
\State \( S \leftarrow S \cup \{x\} \).
\EndFor
\State \textbf{Output}: \( S \).
\end{algorithmic}
\end{algorithm}

Notice that another advantage is that we do not need to assume \( F(A) > 0 \) for \( A \neq \emptyset \) here.

Theorem 3. Algorithm 3 outputs \( S \in \mathcal{B} \) such that

\[ L(S) + 2F(S) \geq L(O) + F(O), \quad \forall O \in \mathcal{B}. \]

Its complexity is \( O(mn) \).

Combining the results before, we get the following theorem.

Theorem 4. With approximation techniques, the cumulative regret for the combinatorial semi-bandits is bounded as

\[ R_T \leq O \left( \sqrt{n \log^2(m) T \log T} \right) \]

with per-round time complexity of order \( O(\log(mt)m^2n) \) (resp., \( O(mn) \)) for \( A = \mathcal{I} \) (resp., \( A = \mathcal{B} \)).

Notice that this new bound is better by a factor \( \sqrt{m}/\log m \) than the one of Kveton et al. (2014) in the case \( A = \mathcal{B} \).

4.3. Budgeted Matroid Semi-Bandits

In this subsection, we extend results of the two previous subsections to budgeted matroid semi-bandits. In budgeted bandits with single resource and infinite horizon (Ding et al., 2013; Xia et al., 2016a), each arm is associated with both a reward and a cost. The agent aims at maximizing the cumulative reward under a budget constraint for the cumulative costs. Xia et al. (2016b) studied budgeted bandits with multiple play, where a \( m \)-subset \( A \) of arms is selected at each round. An optimal (up to a constant term) offline algorithm chooses the same action \( A^* \) within each round, where \( A^* \) is the minimizer of the ratio “expected cost paid choosing \( A^* \)” over “expected reward gained choosing \( A^* \)”.

In the setting of Xia et al. (2016b), the agent observes the partial random cost and reward of each arm in \( A \) (i.e., semi-bandit feedback), pays the sum of partial costs of \( A \) and gains the sum of partial rewards of \( A \). \( A^* \) can be computed efficiently, and a Xia et al. (2016b) give an algorithm based on UCBs. It minimizes the ratio where the averages are replaced by UCBs. We extend this setting to matroid constraints. We assume that total costs/rewards are non-negative linear set functions of the chosen action \( A \). The objective is to minimize a ratio of linear set functions. As previously, two kinds of constraints can be considered for the minimization: either \( A = \emptyset \) or \( A = \mathcal{B} \). Theorem 1 implies that an optimistic estimation of this ratio is of the form \( \frac{L_2 + F_2}{L_2 + F_2} \), where for \( i \in \{1, 2\}, F_i \) is positive (except for \( \emptyset \)), normalized, non-decreasing, submodular; and \( L_i \) are non-negative and linear. \( L_1 - F_1 \) is a high-probability lower bound on the expected cost paid, and \( L_2 + F_2 \) is a high-probability upper bound on the expected reward gained. Notice that the numerator, \( L_1 - F_1 \), can be negative, which can be an incitement to take arms with a high cost/low rewards. Therefore, we consider the minimization of the surrogate \( \frac{L_1}{L_2 + F_2} \). Indeed, \((L_1 - F_1)/(L_2 + F_2)\) is a high probability lower bound on the ratio of expectation, so by monotonicity of \( x \mapsto x^+ \) on \( \mathbb{R} \), \((L_1 - F_1)/(L_2 + F_2)\) is also a high-probability lower bound. We assume \( L_2 \) is normalized, but not necessarily \( L_1 \). \( L_1(\emptyset) \) can be seen as an entry price. When \( L_1 \) is normalized, we assume that \( \emptyset \) is not feasible.

Remark 3. For some \( \lambda \geq 0 \),

\[
\min_{A \in \mathcal{A}} L(\lambda, A) \geq 0 \Rightarrow \lambda \leq \lambda^* ,
\]

\[
\min_{A \in \mathcal{A}} L(\lambda, A) \leq 0 \Rightarrow \left\{ \begin{array}{ll}
\lambda & \geq \lambda^*, \\
\min_{A \in \mathcal{A}} L_1(\lambda, A) - F_1(A) & \leq 0,
\end{array} \right. \text{ which further gives } \lambda^* = 0.
\]

From Remark 3, if it was possible to compute \( \min_{A \in \mathcal{A}} L(\lambda, A) \) exactly, then a binary search algorithm...
Algorithm 4 Binary search for minimizing the ratio \((L_1 - F_1)/(L_2 + F_2)\).

**Input:** \(L_1, L_2, F_1, F_2, \text{ALGO}_\kappa, \eta > 0\).

\[ \delta \leftarrow \frac{\eta}{L_2(L_2 + \kappa F_2(B))} \text{ with } B = \text{ALGO}_\kappa(L_2 + \kappa F_2(B)). \]

\[ A \leftarrow A_0 \in A \{\emptyset\} \text{ arbitrary.} \]

if \(L_\kappa(0, A) > 0\) then

\[ \lambda_1 \leftarrow 0, \quad \lambda_2 \leftarrow \frac{L_1(A) - F_1(A)}{L_2(A) + \kappa F_2(A)}. \]

while \(\lambda_2 - \lambda_1 \geq \delta\) do

\[ \lambda \leftarrow \frac{\lambda_1 + \lambda_2}{2}. \]

\[ S \leftarrow \text{ALGO}_\kappa(-L(\lambda, \cdot)). \]

if \(L_\kappa(\lambda, S) \geq 0\) then

\[ \lambda_1 \leftarrow \lambda. \]

else

\[ \lambda_2 \leftarrow \lambda. \]

\[ A \leftarrow S. \]

end if

end while

Output: \(A\).

would find \(\lambda^*\). This dichotomy method can be extended to \(\kappa\)-approximation algorithms by defining the approximation Lagrangian as

\[ L_\kappa(\lambda, S) \equiv L_1(S) - \kappa F_1(S) - \lambda(L_2(S) + \kappa F_2(S)), \]

for \(\lambda \geq 0\) and \(S \subset [n]\). The idea is to use the following approximation guarantee for a \(\kappa\)-approximation algorithms outputting \(S\),

\[ \min_{A \in \mathcal{A}} L_\kappa(\lambda, A) \leq L_\kappa(\lambda, S) \leq \min_{A \in \mathcal{A}} L(\lambda, A). \]

Thus, for a given \(\lambda\), either the l.h.s is strictly negative or the r.h.s is non-negative, depending on the sign of \(L_\kappa(\lambda, S)\).

Therefore, from Remark 3, a lower bound \(\lambda_1\) on \(\lambda^*\), and an upper bound \(\lambda_2\) on \(\min_{A \in \mathcal{A}} \left(\frac{L_1(A) - \kappa F_1(A)}{L_2(A) + \kappa F_2(A)}\right)^+\) can be computed. The detailed method is given in Algorithm 4. Notice that it takes as input some \(\text{ALGO}_\kappa\), that can be either Algorithm 2 or Algorithm 3, depending on the assumption of the constraint (either \(A = \mathcal{I}\) or \(A = \mathcal{B}\)). We denote the output as \(\text{ALGO}_\kappa(L + F)\), for some linear set function \(L\) and some submodular set function \(F\), for maximizing the objective \(L + F\) on \(A\), so that \(S = \text{ALGO}_\kappa(L + F)\) satisfies \(L(S) + \kappa F(S) \geq \max_{A \in \mathcal{A}} L(A) + F(A)\), i.e., \(\kappa = 2(1 + \varepsilon)\) if \(\text{ALGO}_\kappa = \text{Algorithm 2}, A = \mathcal{I}\) and \(\kappa = 2\) if \(\text{ALGO}_\kappa = \text{Algorithm 3}, A = \mathcal{B}\). In Theorem 5, we state the result for the output of Algorithm 4 and prove it in Appendix E.

**Theorem 5.** Algorithm 4 outputs \(A\) such that

\[ \left(\frac{L_1(A) - (\kappa + \eta) F_1(A)}{L_2(A) + \kappa F_2(A)}\right)^+ \leq \lambda^*, \]

where \(\lambda^*\) is the minimum of \(\frac{L_1 - F_1}{L_2 + F_2}^+\) over \(\mathcal{I}\) if \(\text{ALGO}_\kappa = \text{Algorithm 2}\), and over \(\mathcal{B}\) if \(\text{ALGO}_\kappa = \text{Algorithm 3}\). For \(C_\varepsilon\) given by any algorithm of Table 2, \(F(A) = \max_{B \in C_\varepsilon} A, F(B)\), the complexity is of order \(\log \log(m/\eta)\) times the complexity of \(\text{ALGO}_\kappa\).

### 5. Experiments

We provide experiments for a graphic matroid, on a five nodes complete graph, as did Combes et al. (2015). We thus have \(n = 10, m = 4\). We consider two experiments. In the first one we use \(A = \mathcal{B}\), \(\mu_i = 1 + \Delta I(1 \leq m)\), for all \(i \in [n]\), and in the second, \(A = \mathcal{I}\), where we set \(\mu_i = \Delta I(1 \leq m - 1) - 1\), \(\forall i \in [n]\). We take \(\Delta = 0.1\), with rewards drawn from independent unit variance Gaussian distributions. Figure 1 illustrates the comparison between CUCB and our implementations of ESCB (Combes et al., 2015) using Algorithm 3 (left) and 2 (right, with \(\varepsilon = 0.1\)), showing the behavior of the regret vs. time horizon. We observe that although we are approximating the confidence region within a factor at least 2 (and thus force the exploration), our efficient implementation outperforms CUCB. Indeed, we take advantage (gaining a factor \(\sqrt{m/\log m}\) of the previously inefficient algorithm (that we made efficient) to use reward independence, which the more conservative CUCB is not able to. The latter algorithm has still a better per round-time complexity of \(O(n \log m)\) and may be more practical on larger instances.

![Figure 1](image-url)

**Figure 1.** Cumulative regret for the minimum spanning tree setting in up to \(10^5\) rounds, averaged over 100 independent simulations. **Left:** for \(A = \mathcal{B}\). **Right:** for \(A = \mathcal{I}\).

### 6. Discussion

In this paper, we gave several approximation schemes for the confidence regions and applied them to combinatorial semi-bandits with matroid constraints and their budgeted version. We believe our approximation methods can be extended to approximation regret for non-linear objective functions (e.g., for influence maximization, Wang & Chen, 2018), if the maximization algorithm keeps the same approximation factor for the objective, either with or without the bonus.

References

A. Proof of Proposition 1

Proof. It suffices to maximize on the coordinates of \( \delta \) belonging to \( \mathcal{A} \) (the others being zero). For all \( i \in A \), we let

\[
\eta_i^* \triangleq (1 - \lambda^* g_{i,t}(r - \mu_{i,t-1})) I\{\delta_i^* = r - \mu_{i,t-1}\},
\]

\[
\gamma_i^* \triangleq (\lambda^* g_{i,t}(0) - 1) I\{\delta_i^* = 0\} = -I\{\delta_i^* = 0\}.
\]

For all \( i \in A \), the function \( f_i \) is continuous, non-increasing on \([r, \infty)\), hence so is \( \lambda \mapsto e_A^T (g_{i,t}(f_i(\lambda)))_i \). If \( e_A^T (g_{i,t}(f_i(\lambda^*)))_i > 1 \), then necessarily \( \lambda^* = 0 \). Thus, the following KKT conditions are satisfied:

\[
\lambda^* \left( \sum_{i \in A} g_{i,t}(\delta_i^*) - 1 \right) = 0, \text{ and}
\]

\[
\forall i \in A, \lambda^* g_{i,t}(\delta_i^*) + \eta_i^* - \gamma_i^* = 1,
\]

\[
\eta_i^*(\delta_i^*-r + \mu_{i,t-1}) = 0,
\]

\[
-\gamma_i^*(\delta_i^*) = 0,
\]

which concludes the proof by the convexity of the constraints and the objective function. \( \square \)

B. Proof of Theorem 1

Proof. Let \( t \in \mathbb{N}^+ \). We consider here the restriction of \( g_{i,t} \) to \([0, r - \mu_{i,t-1}]\), that we still denote as \( g_{i,t} \). Notice that for all \( i \in [n] \), \( g_{i,t} \) is either 0 or a bijection on \([0, r - \mu_{i,t-1}]\) by assumption. For \( p = \infty \), we have that

\[
\max_{\delta \in C_i^+ - \mu_{i,t-1}} e_A^T \delta = e_A^T (\min\{g_{i,t}^{-1}(1), r - \mu_{i,t-1}\} I\{N_{i,t-1} \geq 1\} + r I\{N_{i,t-1} = 0\})_i
\]

is a linear set function of \( A \). Assume now that \( p = 1 \). To show the submodularity of \( A \mapsto \max_{\delta \in C_i^+ - \mu_{i,t-1}} e_A^T \delta \) in this case, we will use the notion of polymatroid.

Definition 3 (Polymatroid). A polymatroid is a polytope of the form \( \{ \delta' \in \mathbb{R}_+^n, e_A^T \delta' \leq F(A), \forall A \subset [n] \} \), where \( F \) is a non-decreasing submodular function.

Fact 1 (Theorem 3 of He et al., 2012). Let \( P \) be a polymatroid, and let \( h_1, \ldots, h_n \) be concave functions. Then \( A \mapsto \max_{\delta' \in P} e_A^T (h_i(\delta'))_i \) is submodular.

Notice that \( g_{i,t}^{-1}(\{0\}) = [0, r - \mu_{i,t-1}] \) when \( N_{i,t-1} = 0 \), and that \( g_{i,t}^{-1}(\cdot) \) is a strictly increasing concave function on \([0, g_{i,t}(r - \mu_{i,t-1})]\), as the inverse function of a strictly increasing convex function when \( N_{i,t-1} \geq 1 \). So we can rewrite \( C_i^+ - \mu_{i,t-1} \) as an union of product sets:

\[
C_i^+ - \mu_{i,t-1} = \left\{ \delta \in \prod_{i \in [n]} [0, r - \mu_{i,t-1}], \sum_{i \in [n]} g_{i,t}(\delta_i) \leq 1 \right\} = \bigcup_{\sum_{i \in [n]} \delta_i \leq 1} \prod_{i \in [n]} g_{i,t}^{-1}(\{\delta_i\}).
\]

We can thus rewrite our function as

\[
\max_{\delta \in C_i^+ - \mu_{i,t-1}} e_A^T \delta = \max_{\sum_{i \in [n]} \delta_i \leq 1} \left\{ \max_{\delta' \in \prod_{i \in [n]} [0, g_{i,t}(r - \mu_{i,t-1})]} e_A^T (g_{i,t}^{-1}(\delta'))_i \right\},
\]

with the convention \( g_{i,t}^{-1}(0) = r - \mu_{i,t-1} \) when \( N_{i,t-1} = 0 \).

The constraints’ set \( \left\{ \delta' \in \prod_{i \in [n]} [0, g_{i,t}(r - \mu_{i,t-1})], \sum_{i \in [n]} \delta_i \leq 1 \right\} \) is equal to the intersection between \( \prod_{i \in [n]} [0, g_{i,t}(r - \mu_{i,t-1})] \) and the polymatroid \( \{ \delta' \in \mathbb{R}_+^n, e_A^T \delta' \leq I\{A \neq \emptyset \}, \forall A \subset [n] \} \). This intersection is itself equal to the polymatroid \( \{ \delta' \in \mathbb{R}_+^n, e_A^T \delta' \leq \min_B \{I\{B \neq A \} + e_A^T (g_{i,t}(r - \mu_{i,t-1}))_i \}, \forall A \subset [n] \} \).

Thus, \( \max_{\delta \in C_i^+ - \mu_{i,t-1}} e_A^T \delta \) is the optimal objective value on a polymatroid of a separable concave function, as a function of the index set \( A \). Now, using Fact 1, it is submodular. \( \square \)
C. Proof of Theorem 2

Before proving Theorem 2, we state some well known results about submodular optimization on a matroid.

**Proposition 2.** Let \( A, B \subset [n] \). If \( F \) is submodular, then
\[
\sum_{b \in B \setminus A} (F(B) - F(B \setminus \{b\})) \leq F(B) - F(A \cap B), \quad \sum_{a \in A \setminus B} (F(B \cup \{a\}) - F(B)) \geq F(A \cup B) - F(B).
\]

**Proof.** Let \((b_1, \ldots, b_{|B \setminus A|})\) be an ordering of \( B \setminus A \). Then, by submodularity of \( F \),
\[
\sum_{i=1}^{|B \setminus A|} (F(B) - F(B \setminus \{b_i\})) \leq \sum_{i=1}^{|B \setminus A|} (F(B \setminus \{b_1, \ldots, b_{i-1}\}) - F(B \setminus \{b_1, \ldots, b_i\})) = F(B) - F(A \cap B).
\]
In the same way, let \((a_1, \ldots, a_{|A \setminus B|})\) be an ordering of \( A \setminus B \). Then, by submodularity of \( F \),
\[
\sum_{i=1}^{|A \setminus B|} (F(B \cup \{a_i\}) - F(B)) \geq \sum_{i=1}^{|A \setminus B|} (F(B \cup \{a_1, \ldots, a_i\}) - F(B \cup \{a_1, \ldots, a_{i-1}\})) = F(A \cup B) - F(B).
\]

**Fact 2** (Theorem 1 of Lee et al., 2010). Let \( A, B \in \mathcal{A} \). Then, there exists a mapping \( \alpha : B \setminus A \rightarrow A \setminus B \cup \{\emptyset\} \) such that

- \( \forall b \in B \setminus A, \; A \setminus \{\alpha(b)\} \cup b \in \mathcal{A} \)
- \( \forall a \in A \setminus B, \; |\alpha^{-1}(a)| \leq 1. \)

**Proposition 3.** Let \( A, B \in \mathcal{A} \). Let \( F \) be a submodular function and \( \alpha : B \setminus A \rightarrow A \setminus B \cup \{\emptyset\} \) be the mapping given in Fact 2. Then,
\[
\sum_{b \in B \setminus A} (F(A) - F(A \setminus \{\alpha(b)\} \cup \{b\})) + \sum_{a \in A \setminus B, \; \alpha^{-1}(a) = \emptyset} (F(A) - F(A \setminus \{a\})) \leq 2F(A) - F(A \cup B) - F(A \cap B).
\]

**Proof.** We decompose \( \sum_{b \in B \setminus A} (F(A) - F(A \setminus \{\alpha(b)\} \cup \{b\})) \) into sum of two terms,
\[
\sum_{b \in B \setminus A} (F(A) - F(A \setminus \{\alpha(b)\})) + \sum_{b \in B \setminus A} (F(A \setminus \{\alpha(b)\}) - F(A \setminus \{\alpha(b)\} \cup \{b\})).
\]
Remark that the first part is equal to
\[
\sum_{a \in \alpha(B \setminus A)} (F(A) - F(A \setminus \{a\})) = \sum_{a \in A \setminus B, \; \alpha^{-1}(a) \neq \emptyset} (F(A) - F(A \setminus \{a\})).
\]
Thus, together with \( \sum_{a \in A \setminus B, \; \alpha^{-1}(a) = \emptyset} (F(A) - F(A \setminus \{a\})) \), we get that
\[
\sum_{b \in B \setminus A} (F(A) - F(A \setminus \{\alpha(b)\} \cup \{b\})) + \sum_{a \in A \setminus B, \; \alpha^{-1}(a) = \emptyset} (F(A) - F(A \setminus \{a\}))
\]
is equal to
\[
\sum_{a \in A \setminus B} (F(A) - F(A \setminus \{a\})) + \sum_{b \in B \setminus A} (F(A \setminus \{\alpha(b)\}) - F(A \setminus \{\alpha(b)\} \cup \{b\})).
\]
Finally, we upper bound the first term by \( F(A) - F(A \cap B) \) using first inequality of Lemma 2, and the second term by \( F(A) - F(A \cup B) \) using first, the submodularity of \( F \) to remove \( \alpha(b) \) in the summands, and then the second inequality of Lemma 2. \( \square \)
Proof of Theorem 2. The proof is divided into two parts:

Approximation guarantee If Algorithm 2 outputs $\emptyset$ before entering in the while loop, then by submodularity, for any $S \in \mathcal{I}$,

$$ (L + F)(S) \leq \sum_{x \in S} (L + F)(\{x\}) \leq 0. $$

Thus, $\emptyset$ is a maximizer of $L + F$.

Otherwise, the output $S$ of Algorithm 2 satisfies the local optimality of the while loop. We apply Proposition 3 with $A = S$ and $B = O$ for $L$ and $F$ separately,

$$ \sum_{b \in O \setminus S} (L(S) - L(S \setminus \{\alpha(b)\} \cup \{b\})) + \sum_{a \in S \setminus O, \alpha^{-1}(a) = \emptyset} (L(S) - L(S \setminus \{a\})) \leq 2L(S) - L(S \cup O) - L(S \cap O), $$

$$ \sum_{b \in O \setminus S} (F(S) - F(S \setminus \{\alpha(b)\} \cup \{b\})) + \sum_{a \in S \setminus O, \alpha^{-1}(a) = \emptyset} (F(S) - F(S \setminus \{a\})) \leq 2F(S) - F(S \cup O) - F(S \cap O). $$

Then, we sum these two inequalities,

$$ \sum_{b \in O \setminus S} ((L + F)(S) - (L + F)(S \setminus \{\alpha(b)\} \cup \{b\})) + \sum_{a \in S \setminus O, \alpha^{-1}(a) = \emptyset} ((L + F)(S) - (L + F)(S \setminus \{a\})) $$

$$ \leq 2(L + F)(S) - (L + F)(S \cup O) - (L + F)(S \cap O) $$

$$ = 2F(S) - F(S \cup O) - F(S \cap O) + L(S) - L(O), $$

where the last equality uses linearity of $L$. Since $F$ is increasing and non-negative, $F(S \cup O) + F(S \cap O) \geq F(O)$, and we get

$$ \sum_{b \in O \setminus S} ((L + F)(S) - (L + F)(S \setminus \{\alpha(b)\} \cup \{b\})) + \sum_{a \in S \setminus O, \alpha^{-1}(a) = \emptyset} ((L + F)(S) - (L + F)(S \setminus \{a\})) $$

$$ \leq 2F(S) - F(O) + L(S) - L(O). $$

From the local optimality of $S$, the left hand term in this inequality is lower bounded by

$$ \sum_{b \in O \setminus S} \frac{-\varepsilon}{m} F(S) + \sum_{a \in S \setminus O, \alpha^{-1}(a) = \emptyset} \frac{-\varepsilon}{m} F(S) \geq -2\varepsilon F(S). $$

The last statement finishes the proof for the approximation inequality.

Time complexity Computing $S_0$ has a negligible complexity compared to the while loop. The following lemma gives a characterization of $S_0$.

Lemma 2. $S_0 \in \arg \max \{L(A), A \in \mathcal{I}, (F + L)(A) > 0\}.$

Proof. From Algorithm 2, if $S_{\text{init}} \neq \emptyset$, then $S_0 = S_{\text{init}}$ and $L(S_0) = \max_{A \in \mathcal{I}} L(A) \geq 0$. Thus, $F(S_0) > 0$ by assumption on $F$, giving $(F + L)(S_0) > 0$, which ends the proof. If $S_{\text{init}} = \emptyset$, then $L(S_0) = \max \{L(\{\ell\}), \{\ell\} \in \mathcal{I}, (F + L)(\{\ell\}) > 0\}$. Let $A \in \arg \max \{L(A), A \in \mathcal{I}, (F + L)(A) > 0\}$. $A$ is clearly non-empty, and by submodularity of $F + L$, there exists $x \in A$ such that $(F + L)(\{x\}) > 0$. $L$ is non-increasing from $S_{\text{init}} = \emptyset$, so we get $L(\{x\}) \geq L(A)$, which means there is a singleton $\{x\}$ in $\arg \max \{L(A), A \in \mathcal{I}, (F + L)(A) > 0\}$, so $S_0 \in \arg \max \{L(A), A \in \mathcal{I}, (F + L)(A) > 0\}$, which finishes the proof.

From this lemma, necessarily $L(S_\ell) \geq L(S_0)$ for every iterations $\ell \geq 1$, since the sequence $(L(S_\ell) + F(S_\ell))_\ell$ is increasing, and thus $(F + L)(S_\ell) > 0$, for $\forall \ell \geq 1$. At each iteration $\ell \geq 1$, Algorithm 2 constructs $S_\ell$ such that

$$ F(S_\ell) > \left(1 + \frac{\varepsilon}{m} \right) F(S_{\ell-1}) + L(S_{\ell-1}) - L(S_\ell). $$
Thus, we must have
\[ F(S_\ell) - \left(1 + \frac{\varepsilon}{m}\right)\ell F(S_0) \geq \sum_{j=1}^{\ell} (1 + \frac{\varepsilon}{m})^{\ell-j} (L(S_{j-1}) - L(S_j)) \]
\[ = L(S_0) \left(1 + \frac{\varepsilon}{m}\right)^{\ell-1} - \frac{\varepsilon}{m} \sum_{j=1}^{\ell-1} L(S_j) \left(1 + \frac{\varepsilon}{m}\right)^{\ell-j-1} - L(S_\ell) \]
\[ \geq L(S_0) \left(1 + \frac{\varepsilon}{m}\right)^{\ell-1} - \frac{\varepsilon}{m} \sum_{j=1}^{\ell-1} L(S_0) \left(1 + \frac{\varepsilon}{m}\right)^{\ell-j-1} - L(S_0) = 0, \]
where the last inequality uses \( L(S_0) \geq L(S_\ell), \forall \ell \geq 1 \). This gives the following upper bound on the number of iteration \( \ell \):
\[ \ell \leq \frac{\log \left( \frac{F(S_\ell)}{F(S_0)} \right)}{\log \left( 1 + \frac{\varepsilon}{m} \right)} \leq \frac{\log \left( \max_{A \in A} \frac{F(A)}{F(S_0)} \right)}{\log \left( 1 + \frac{\varepsilon}{m} \right)}. \]

Finally, the result follows remarking that time complexity per iteration is \( O(mn) \).

\[ \square \]

D. Proof of Theorem 3

As we did in the previous section, before starting the proof of Theorem 3, we state some useful results.

**Fact 3** (Brualdi’s lemma). Let \( A, B \in B \). Then, there exists a bijection \( \beta : A \rightarrow B \) such that
\[ \forall a \in A, A \setminus \{a\} \cup \{\beta(a)\} \in B. \]

Furthermore, \( \beta \) is the identity on \( A \cap B \).

**Proof.** A proof is given by Brualdi (1969) and is also proved by Schrijver (2008), as Corollary 39.12a.

**Proposition 4.** Let \( A, B \in B \). Let \( F \) be a submodular function and \( \beta : A \rightarrow B \) be the mapping given in Fact 3. Let \( a_1, \ldots, a_k \) be elements of \( A \), and \( A_i = \{a_1, \ldots, a_i\} \). Then,
\[ \sum_{i \in [k]} (F(A_i) - F(A_{i-1} \cup \{\beta(a_i)\})) \leq 2F(A) - F(A \cup B) - F(\emptyset). \]

**Proof.** We can split \( \sum_{i \in [k]} (F(A_{i-1} \cup \{a_i\}) - F(A_{i-1} \cup \{\beta(a_i)\})) \) into two terms,
\[ \sum_{i=1}^{k} (F(A_{i-1} \cup \{a_i\}) - F(A_{i-1})) + \sum_{i=1}^{k} (F(A_{i-1}) - F(A_{i-1} \cup \{\beta(a_i)\})). \]
The first term is equal to \( F(A_k) - F(\emptyset) \). Using submodularity of \( F \), the second term is upper bounded by
\[ \sum_{i=1}^{k} (F(A_m) - F(A_m \cup \{\beta(a_i)\})), \]
which is upper bounded by \( F(A_k) - F(A_k \cup B) \) thanks to Proposition 2 and its second inequality.

**Proof of Theorem 3.** The time complexity proof is trivial. Let \( S_i \triangleq \{s_1, \ldots, s_i\} \) be the set maintained in Algorithm 3 after \( i \) iterations. Instantiating Proposition 4 with \( A_i = S_i \) and \( B = O \), we have
\[ \sum_{i \in [k]} (F(S_i) - F(S_{i-1} \cup \{\beta(s_i)\})) \leq 2F(S) - F(S \cup O) - F(\emptyset). \tag{5} \]
Furthermore, we also have, by linearity of $L$, and bijectivity of $\beta$,
\[
\sum_{i \in [k]} (L(S_i) - L(S_{i-1} \cup \{\beta(s_i)\})) = \sum_{i \in [k]} (L(\{s_i\}) - L(\{\beta(s_i)\})) = L(S) - L(O).
\] (6)
Thus, we can sum up (5) and (6) to get
\[
\sum_{i \in [k]} ((L + F)(S_i) - (L + F)(S_{i-1} \cup \{\beta(s_i)\})) \leq 2F(S) - F(S \cup O) - F(\emptyset) + L(S) - L(O)
\]
\[
\leq 2F(S) - F(O) + L(S) - L(O),
\]
where the last inequality uses the fact that $F$ is increasing and $F(\emptyset) = 0$. We finish the proof remarking that by definition of Algorithm 3, $(L + F)(S_i) - (L + F)(S_{i-1} \cup \{\beta(s_i)\}) \geq 0$. \hfill \Box

**E. Proof of Theorem 5**

*Proof.* Let $A$ be the output of Algorithm 4 and let
\[
\mathcal{L}_{\kappa_1, \kappa_2}(\lambda, S) \triangleq L_1(S) - \kappa_1 F_1(S) - \lambda (L_2(S) + \kappa_2 F_2(S)).
\]
Recall that $\mathcal{L}_\kappa = \mathcal{L}_{\kappa, \kappa}$. Algorithm 4 satisfies either $\mathcal{L}_\kappa(0, A_0) \leq 0$ — in which case Theorem 5 is trivial since
\[
\left( \frac{L_1(A) - (\kappa + \eta) F_1(A)}{L_2(A) + \kappa F_2(A)} \right)^+ = \lambda^* = 0
\]
— or $\mathcal{L}_\kappa(0, A_0) > 0$, in which case we have
\[
0 > \mathcal{L}_\kappa(\lambda_2, A) \geq \mathcal{L}_{\kappa + \eta, \kappa}(\lambda_2 - \delta, A) \geq \mathcal{L}_{\kappa + \eta, \kappa}(\lambda_1, A) \geq \mathcal{L}_{\kappa + \eta, \kappa}(\lambda^*, A).
\] (7)
The first inequality is comes from the update of $\lambda_2$: Notice that before the while loop, we have
\[
\lambda_2 = \frac{L_1(A_0) - F_1(A_0)}{L_2(A_0) + F_2(A_0)} > \frac{L_1(A_0) - \kappa F_1(A_0)}{L_2(A_0) + \kappa F_2(A_0)} > 0,
\]
since $F_2(A_0) > 0$, so $0 > \mathcal{L}_\kappa(\lambda_2, A_0)$ multiplying by $L_2(A_0) + F_2(A_0)$ on both sides. Notice that in particular, this inequality gives that $A \neq \emptyset$.

The second inequality follows from
\[
\delta = \frac{\eta \min_{s \in A} F_1(\{s\})}{L_2(B) + \kappa^2 F_2(B)} \leq \frac{\eta F_1(A)}{L_2(A) + \kappa F_2(A)} \quad \text{since } A \neq \emptyset \text{ and } L_2(B) + \kappa^2 F_2(B) \geq L_2(A) + \kappa F_2(A).
\]
Thus, multiplying by $L_2(A) + \kappa F_2(A) > 0$, and adding $L_1(A) - \kappa F_1(A) - \lambda_2(L_2(A) + \kappa F_2(A))$ gives
\[
L_1(A) - (\kappa + \eta) F_1(A) - (\lambda_2 - \delta)(L_2(A) + \kappa F_2(A)) \leq L_1(A) - \kappa F_1(A) - \lambda_2(L_2(A) + \kappa F_2(A)),
\]
i.e., $\mathcal{L}_{\kappa + \eta, \kappa}(\lambda_2 - \delta, A) \leq \mathcal{L}_\kappa(\lambda_2, A)$.

The third inequality uses $\lambda_2 - \lambda_1 \leq \delta$, and the last inequality uses $\lambda_1 \leq \lambda^*$. Indeed, since $\mathcal{L}_\kappa(\lambda_1, S) \geq 0$, the approximation relation given by $\text{ALGO}_\kappa$,
\[
\mathcal{L}_\kappa(\lambda_1, S) \leq \mathcal{L}(\lambda_1, O),
\]
where $O$ is the minimizer of $\left( \frac{L_2 - F_2}{L_2 + F_2} \right)^+$ (for the constraints considered by $\text{ALGO}_\kappa$), gives $0 \leq \mathcal{L}(\lambda_1, O)$. Thus,
\[
\mathcal{L}^+(\lambda_1, O) \triangleq (L_1(O) - F_1(O))^+ - \lambda_1(L_2(O) + F_2(O)) \geq \mathcal{L}(\lambda_1, O) \geq 0.
\]
Finally, since $L_2(O) + F_2(O) > 0 (O \neq \emptyset)$, we have $\lambda_1 \leq \lambda^*$.

In (7), since $A \neq \emptyset$, we have $\frac{L_1(A) - (\kappa + \eta) F_1(A)}{L_2(A) + \kappa F_2(A)} \leq \lambda^*$ and therefore, $\left( \frac{L_1(A) - (\kappa + \eta) F_1(A)}{L_2(A) + \kappa F_2(A)} \right)^+ \leq \lambda^*$.

The time complexity for the binary search is $O(\log(1/\delta)) \leq O(\log(mt/\eta))$ for $C_t$ given by any algorithm of Table 2, and $F(A) = \max_{\delta \in \mathcal{C}_t^+ - \mathcal{C}_{t-1}} e_{\mathcal{N}}^T \delta$. \hfill \Box
